Vinyl cyanide 193 nm photodissociation has been studied using Chirped-Pulse Millimeter-Wave (CPmmW) spectroscopy. \( J = 0 - 1 \) transitions of more than 30 vibrationally excited states of the HCN and HNC products have been recorded and assigned within the 7 GHz wide chirp range. Bending excitations of HCN up to \( v_2 = 14 \), leading toward the HCN \( \leftrightarrow \) HNC isomerization transition state, are detected and interpreted in terms of their electric quadrupole, \((eQq)_N\), and rotational, \(B_v\), constants. The photolysis reaction transition states were probed using both normal vinyl cyanide, \( \text{CH}_2=\text{CHCN} \), and its singly-deuterated isotopologue, \( \text{CH}_2=\text{CD}_2 \). The observed difference in the vibrational population distribution (VPD) obtained from the integrated intensities of the HCN and DCN products from the \( \text{CH}_2=\text{CHCN} \) vs. \( \text{CH}_2=\text{CD}_2 \) photolysis reactions, suggests the relative unimportance of the three-center elimination mechanism for HCN production. On the other hand, the similarity in the observed VPD and overall intensities of HCN from \( \text{CH}_2=\text{CHCN} \) and \( \text{CH}_2=\text{CD}_2 \) photolysis suggests four-center elimination as the major mechanism leading to the HCN product. Additional \( J - (J + 1) \) transitions would be required to characterize both the vibrational and the rotational state distributions of the products, which would permit more complete characterization of the transition state(s).
