

HIGH-RESOLUTION INFRARED SPECTRA OF THE METHYL C-H-VIBRATIONS IN ETHYL RADICAL

T. HÄBER, A. C. BLAIR, and D. J. NESBITT, *JILA, University of Colorado, Boulder, Colorado 80309-0440*.

All three CH-stretch vibrations of the methyl group in ethyl radical have been measured using high-resolution infrared spectroscopy in a slit supersonic discharge expansion source. Rotational assignment and analysis has been performed on each of these spectra providing rotational and centrifugal-distortion constants. We see one A-type band, which corresponds nominally to the symmetric stretch vibration, with a band origin at $2854.1027(3) \text{ cm}^{-1}$. Instead of a nominally degenerate vibration, the methyl asymmetric CH stretch is split into two B- and C-type bands with a separation of 124.5361 cm^{-1} due to internal rotation around the C-C bond. When compared to the splitting in nitromethane,^{ab} an analogous model system for hindered internal rotation, this separation is substantially larger.
