IR absorption has been recorded for the conversion of benzyl alcohol to benzyl benzoate on a nickel oxide surface by surface plasmon-mediated resonance. By activating the surface with OH groups, benzyl alcohol undergoes several intermediate steps that are recorded in time with benzyl benzoate forming the final product. Surface plasmon-mediated transmission resonance is a very sensitive technique that reveals dramatic changes at the metal-dielectric interface for the chemistry involved. Molecular absorption in the transmission spectra were analyzed to reveal those intermediate steps while obtaining an enhanced infrared absorption spectrum of benzyl benzoate.
